TELEPHONE SYSTEM WITH SELECTIVE CODE COMPRESSION AND REGISTER RECYCLE

Robert C. Avery, Jackson Heights, and Anthony Majlinger, Long Island City, N.Y., assignors to Bell Telephone Laboratories, Incorporated, New York, N.Y., a corporation of New York

Filed July 27, 1960, Ser. No. 45,705

7 Claims. (Cl. 179-18)

This invention relates to telephone systems employing automatic switching equipment for the establishment of communication paths. In particular, the invention provides new and improved means for handling customer dialed toll calls.

At the present time there are plans for converting existing switching equipment to handle direct distance dialed calls, hereinafter referred to as DDD calls. The directing codes or digits required for such toll switching purposes have been arrived at by dividing the nation into areas, the size of each area generally depending upon the number of telephone stations therein, and each area being assigned a 3-digit area code. These 3-digit area codes are added to the directory designations of each subscriber connected to the system. In order to distinguish the 3-digit area codes of a subscriber's designation, the area code designations have been selected so as to have the second digit, of the three digits comprising each area code, always a "1" or a "0." The first digit of an area code may be any digit except a "0" or a "1," the "0" being omitted since it might be confused with the digit "0" customarily dialed by a subscriber to reach an operator and the digit "1" being omitted to avoid the possibility of the false transmission of a "1" as the first digit through switch-hook fumbling. The numbering plan currently in existence therefore provides that area codes may be X0X or X1X, where X is any of the digits 2-9 and in the third position may also include 0.

One of the requisites for processing customer toll dialing is that the equipment in local central offices must be capable of receiving and registering 10 or 11 digit designations and of retransmitting them to a toll switching system. Certain of the automatic telephone systems presently in use, for example systems of the panel and crossbar type, initially were designed to receive and register only seven or eight digits of a subscriber number. These systems have subsequently been modified by the addition of auxiliary senders. In general, an auxiliary sender circuit is common to a plurality of senders and is connectable thereto to provide additional register capacity in the event that a pretranslation of the first three digits indicates that the call is of a DDD variety.

In a typical local automatic switching telephone office, of the type known as a crossbar office, such as shown in United States Patent 2,235,803 granted to W. W. Carpenter on March 18, 1941, when a subscriber originates a call the calling line is automatically connected to an idle district junctor and to an idle subscriber sender. The subscriber sender receives and registers called line designations as dialed by the calling subscriber but is equipped to register a maximum of eight digits. After the first three digits have been registered, identifying the office to which the call is directed, the sender is connected to an idle marker and passes these three digits to the marker. The marker translates the digits into a routing indication from which it derives information which it uses in selecting an idle trunk leading to the identified office and in connecting the selected trunk with the district junctor to which the calling line has already been connected. At the same time, the marker derives information required by the sender at the sending office as to the class of call, etc. which it passes back to the subscriber sender, fol-

2

lowed by a release signal. From the class of call indication the subscriber sender determines the type of outpulsing to be used in controlling the called office, sets up the required type of control circuit passing by way of the district junctor and the selected outgoing trunk to the distant office and prepares the proper pulsing equipment. This control circuit, which is used for both testing the condition of the trunk and for transmitting the designation to the distant office, is usually called the "fundamental circuit."

United States Patent 2,867,690, granted to C. O. Parks on January 6, 1959, discloses an auxiliary sender arrangement which may or may not be inserted in the fundamental circuit in accordance with whether the call is to another toll area, herein called a foreign area, or is to the local area. With the addition of such circuitry therefore, DDD calls may be handled by local offices which would otherwise have insufficient sender register capacity.

Prior to the institution of direct distance dialing in certain thickly populated areas of the country, for example, the area surrounding large cities, the density of telephone traffic required the establishment of special trunking facilities within the areas themselves, in spite of the fact that the relatively short distances were involved. When the areas for direct distance dialing purposes were established, it was found necessary to divide such thickly populated areas, placing a portion thereof in one DDD area and other portions in other DDD areas. Utilization of the standard central office modifications wherein auxiliary sender registering equipment is used to aid in the establishment of calls between such DDD areas does not take advantage of the many existing specialized trunk circuits.

When using auxiliary senders, the common practice is to utilize an auxiliary sender and subsequently forward all calls to the designated area via a central facility. In some geographic locations, due to natural growth and development the inter-area traffic is a substantial portion of all calls handled. This being so, considerable expense is required for additional auxiliary sender equipment. It has been found that the majority of inter-area calls are either between adjacent areas, or between areas previously served by direct trunking facilities as mentioned above. By intercepting such calls and routing them directly to the designated areas, it becomes possible to eliminate the need for the major portion of the auxiliary sender equipment, thereby effecting considerable economies.

A code compressor, designed to replace auxiliary sender equipment in the instance described, is disclosed and claimed by R. C. Avery in patent application Serial No. 45,706, filed concurrently herewith. The instant invention is an improvement upon the code compressor circuitry therein claimed, whereby the arrangement is more efficient and more effectively adapted to existing equipment and practices.

In view of the dynamic nature of telephone industry needs it is not possible to accurately predict the exact future requirements for facilities of the nature described. Consequently, an object of the invention is to facilitate expansion of the code compressor capacity with a minimum of circuit modification.

Although the code compressor circuitry of this invention has to a large extent eliminated most auxiliary sender equipment, such equipment has been retained for routing calls to remote foreign areas. Because auxiliary senders are still available for certain normal operations it is found advantageous to also use them as stand-by facilities. Such a utilization is necessary, for instance, in the event a code compressor fails to complete its function prior to receipt of a fourth digit of the directing code.

Another object of the invention is to provide for alternate routing of calls via auxiliary sender equipment in the event of delay in code compressor action.

The requirements of standard operating procedure also create the need for alternative handling of calls. For example, at the present time "special service codes" are used to obtain access to particular stations at the central office. These codes take the form of "411" for information service, "211" for long distance service, etc. Because these codes have a "1" designation for the B digit they will cause connection of a code compressor upon registration. In order to reserve the area code handling capacity of the code compressor, alternative means are provided in this invention for such directing codes.

Still another object of the present invention is to service "special service codes" without undue delay if a compressor is not available.

Yet another problem encountered in using common code compression techniques, is the equitable allotment of code compressor time to all subscribers. Thus, another object of the invention is the provision of a traffic control arrangement whereby all subscriber senders are given access to code compressors without undue discrimination.

The invention features encoding of a decoder-translator output into a 2-out-of-5 code, storing the code, checking its validity, and transmitting the import thereof to a marker circuit.

Another feature of the invention includes means operative in response to reception of a fourth digit prior to completion of the code compression cycle to direct subsequent digits to the auxiliary sender equipment.

As previously pointed out, on some calls (e.g. special service calls), the directing code comprises only three digits, the second of which may be a "1." A feature of the invention, directed toward proper treatment of such calls, lies in means for abandoning a request for a compressor by use of the auxiliary sender routing signal when excessive delay is encountered. This permits the call to proceed.

Still another feature of the invention is means for sequencing connections between connectors and common code compressors whereby each connector is permitted only one turn at a time.

Fundamentally, the invention comprises circuitry operative in conjunction with a code compression system as claimed in patent application Serial No. 45,706, filed concurrently herewith. This circuitry permits increased code compressor capacity, overflow procedures in the event of trouble, special procedures upon receipt of special service codes or the like, and selective connection to the code compressors to yield equitable distribution of compressor time to all subscriber senders.

The foregoing as well as additional objects and features will be clearly understood and appreciated from the following description in conjunction with the drawings wherein:

FIG. 1 is a block diagram of an embodiment of the invention.

FIG. 1A shows the manner in which the circuit schematic sheets should be arranged.

FIGS. 2 and 3 are circuit schematics of typical recycle circuits as connected for example to elements of a crossbar subscriber sender.

FIGS. 4-9, 14, and 17 are circuit schematics of portions of the connector circuitry.

FIGS. 10-13, 15, and 16 are circuit schematics of the compressor arrangement including three decoder-translators which serve a block of 200 subscriber senders.

FIG. 18 is a sequence chart showing the normal sequence of operation of the disclosed circuitry upon receipt of a regular DDD call.

For purposes of description the present invention is

disclosed as embodied in a typical crossbar switching system, such as described in the aforementioned Carpenter patent, 2,235,803, as modified by the auxiliary sender circuit described in the aforementioned Parks patent, 2,867,690. It should be understood however, that the teachings herein are also applicable, with minor modifications to panel systems.

The basic circuit units and their functional interrelationships may be recognized and understood from a consideration of FIG. 1, wherein it may be seen that the illustrative embodiment contains circuitry for providing preselected area code compression for two hundred subscriber senders. Each individual sender 200 is connected to a distinct recycle circuit 201. A group of ten senders is served by one connector circuit 400 and access thereto is obtained via a sender preference circuit 700, individual thereto. Each connector circuit 400, in turn, has access to three decoder translators 1200, 1500, or 1501. In order to determine which connector will first be served and which compressor will be employed, connector preference circuits 801, 802, and 803, and compressor selector 809, are provided, respectively.

When any DDD code is dialed into a subscriber sender, the registration of the "0" or "1" in the B digit register activates the subscriber sender recycle circuit. Upon activation, the recycle circuit initiates opening of the marker start lead to prevent passage of these code digits thereto for translation or other operations; actuates the sender preference circuit thereby bidding for access to the common connector serving its sender group; and applies a start signal to the compressor selecting circuits to secure the services of an idle compressor. As will be noted in the following description, the latter two operations are performed coincidentally in order to minimize the total operating time.

The sender preference circuits insure access to the connector serving their group of subscriber senders according to a predetermined order of preference among the senders in each group. Once association with a connector is achieved all connectors bid for access to an idle compressor by means of similar preference circuitry.

If the area code is one of a preselected group of codes (e.g. that of an adjacent area), it is translated into a discrete 2-out-of-5 signal by the decoder-translator and transmitted to the recycle circuit for subsequent use by the marker. If the area code does not fall within the preselected group a request for association with an auxiliary sender is transmitted via the recycle circuit.

Before giving a detailed description of the operation of the circuit, the conventions employed in the associated drawings, FIGS. 2-17 will be explained to make the description more easily understood.

The detached contact method of illustration, now quite widely understood, has been adopted. In this method the relay winding is shown physically separated from the contacts controlled thereby. This permits placement of the contacts at locations in the circuit drawings where the functions they perform are visually pertinent and avoids the necessity of employing a large number of needlessly long connecting lines. With this system of representation, normally closed contacts are illustrated by a short line perpendicular to the conductor to which they are connected and normally open contacts are illustrated by a pair of diagonal lines forming an "X," intersecting the conductor to which they are connected. Contacts are identified by the same designation as the relay by which they are controlled, for example: FIGS. 5 and 6 contain a plurality of normally open contacts of relays 7SA—vertically disposed along the left-hand edges thereof; FIG. 10 contains a plurality of normally closed contacts associated with relays 12CAS-1, 13STB, 13SK, 13TK, and 13RR, connected in series between conductor 834 and ground; and FIG. 5 shows a plurality of transfer contacts associated with relays 8CS0, 8CS1, and 8CS2 in the upper right quadrant thereof.

An additional feature of the drawing is that the relays, in addition to containing numerical designations which represent the figure in which they appear, also contain letter designations which, in many instances, are descriptive of the relay functions and which may be related thereto by reading the description. For example, the relay appearing in the lower right-hand corner of FIG. 2 is designated 2CST-0. This indicates that the relay appears in FIG. 2, has the function of "Compressor Start," and is part of the recycle circuit for subscriber sender "0."

It may also be noted that the elements in the subscriber sender circuit located on the left-hand side of FIG. 2 contain numerical designations which are distinct from their functional designations. In general, the numerical designations are identical to those appearing in the aforementioned Patent No. 2,235,803. The only exception to this occurs in the case of relay AS, the counterpart of which appears in FIG. 5 of aforementioned Patent 2,867,690.

Further, in order to avoid duplication of drawings, in instances where circuitry is identical to that already present in the drawings, it has been illustrated as a box, labeled descriptively and having input and output leads identical to a similar box in which all circuit details are illustrated. Examples of this appear in FIGS. 2 and 3.

As a further aid in understanding the circuit operation of the illustrative embodiment a sequence chart is presented in FIG. 18. On this chart, time is represented as increasing from an initially zero time at the top to a subsequent time at the bottom; relays are indicated by their function designations and are physically disposed in accord with the portion of the circuit in which they operate; and the energization of a relay is depicted by an "X," whereas the de-energization of a relay is depicted by a line perpendicular to the sequence line. A more detailed understanding of the sequence chart may be had from the description hereinafter.

General Circuit Functions

The functions of various parts of the disclosure are illustrated in FIG. 2 which comprises elements of a cross-bar subscriber sender pertinent to the operation of the invention. A detailed description of these elements, their operation, and their interrelationships, may be obtained from Patent No. 2,235,803, granted March 18, 1941, to W. W. Carpenter, and Patent No. 2,867,690, granted January 6, 1959, to C. O. Parks. The disclosures of these patents are hereby incorporated by reference as though fully set forth herein.

FIG. 2 also illustrates a subscriber sender recycle circuit. This circuit initiates connection of its associated sender to a code compressor circuit and in addition operates under the control of the seized code compressor to inform a marker that the call is to a particular preselected area, or to some other area (including the local area).

FIGS. 4-9, 14, and 17 show portions of the connecting circuits used in the invention. FIG. 4 discloses timing circuits used in monitoring the establishment of connections between sender recycle circuits and their connectors. FIGS. 5 and 6 show the contact arrangements which are responsible for establishing paths between the subscriber sender recycle circuits and a compressor. FIG. 7 discloses three typical stages of a ten-stage preference chain used to establish the order of precedence in which senders of the illustrated group will be served. FIGS. 8 and 9 show three typical connector control groups, the function of which is to preferentially connect their associated connecting relays to an idle compressor. FIGS. 14 and 17 contain control circuitry associated with the connector circuits.

FIGS. 11 and 12 illustrate the component parts of the relay decoder-translating arrangement used herein. Each compressor contains one such arrangement, which in general is controlled and maintained by the circuits shown in FIG. 13. Busy indications and timing and alarm func-

tions for each compressor are performed by the circuitry shown in FIG. 10.

Operation on a Selected Area Call

In order to describe the functioning of the circuit in response to a call, it will be assumed that the subscriber sender in FIG. 2 is the one into which an area code has been dialed. This subscriber sender is designated "cross-bar subscriber sender 0." There are ten such senders in a group as shown in FIG. 3 by representing the second and last senders as boxes 346 and 347, respectively.

Registration of three digits in the registers of subscriber sender 0 causes the operation of the CL (3812) relay therein, as fully described in aforementioned Patent No. 2,867,690. In the event the B digit is either "0" or "1," the energizing ground applied to the winding of the CL (3812) relay is also applied through the "0" or "1" cross-point of the B register, conductor 211, diode 229, normal contacts 2CC0, 2CC1, 2CC4, 2CC7, 2ASR, 2OFR, 2CST-0, 2TRL, and the winding of relay 2CST-0 to negative battery, operating relay 2CST-0. Relay 2CST-0 establishes a holding path for itself comprising: negative potential, the winding thereof, normal contacts 2TRL, resistor 248, normal contacts 2OFR, 2ASR, 2CC7, 2CC4, 2CC1, 2CC0, diode 230, operated contacts 2CST-0, conductors 239 and 235, operated off-normal contacts ON1, and ground. Another holding path is established through normal contacts 2RCY, which are connected in parallel with the above-described 2CC- relays. Upon operation, relay 2CST-0, inserts resistance 248 in series with its winding. This is a common practice for preventing damage to the winding in the event the relay remains operated for an undue length of time. Similar protective circuitry is used throughout the present disclosure.

Operation of compressor start relay 2CST-0 simultaneously starts the recycle end of the connector circuit, the compressor end of the connector circuit, and a timing circuit. The timing circuit under normal circumstances does not interfere with subsequent operations and therefore will not be discussed at this time. Its function is to provide alarm and alternate operating means in the event of a trouble condition.

Selection of a Subscriber Sender

Closure of contacts 2CST-0 in FIG. 7 provides an operating path from negative potential through the winding of sender start relay 7SS-0, operated contacts 2CST-0, normal contacts 7CBY, through a preference chain (conductors 714 and 715) consisting of the normal contacts of the 7SS- relays associated with succeeding senders in the instant sender group, and over conductor 713 to ground at 716, operating relay 7SS-0. The preference chain is arranged in a conventional manner in order to give preference to the 7SS- relay closest to the "9" end. Thus, if the 3CST-1 relay associated with the subscriber sender shown in FIG. 3 were operated, it would preclude operation of relay 7SS-0 due to the operation of transfer contacts of relay 7SS-1 through which relay 7SS-0 must be grounded. In the event two senders bid for service by a connector simultaneously or within a short time interval, the circuitry, as developed, is fast enough to serve the sender having preference and then serve the second. The second sender in this case "holds-on" by maintaining its CST relay operated.

Operation of relay 7SS-0 closes an obvious locking path for itself and operates transfer contacts permitting establishment of an energization path from negative potential through the winding of relay 7SA-0, operated contacts of relay 7SS-0 to ground at point 716, operating relay 7SA-0. The 7SA- relays are connected in a preference chain which is directly opposed to that of the 7SS- relays. Thus, the operating path of a 7SA- relay is through the normal contacts of preceding 7SS- relays to ground, giving preceding 7SA- relays preference.

Operation of relay 7SA-0 closes a plurality of paths

from the recycle circuit of sender 0 to the connector. This is shown in FIG. 5 wherein the normally open contacts appear in a plurality of connecting lines. The effect of operating relay 7SA-0 is to provide connection between cables 212 and 510 and between a plurality of recycle control leads and cable 511. The connections between the recycle circuit and connector, necessary for transmission of the digital information and the receipt of instructions in relation thereto, are now established.

Selection of a Code Compressor

Simultaneously with the operation of any 7SS- relay, a start signal is applied by the compressor start circuit in FIG. 8 to an appropriate compressor start relay 8CS-, in order to effect seizure of a code compressor.

Before describing actual circuit operation in the connector, recall the general scheme. A single connector serves each group of the senders. The sender served at any one time is determined by the sender preference arrangement just discussed. The connector being used must now compete with the other nineteen connectors of the embodiment for association with a code compressor to act upon the digits stored in the selected sender. The circuitry for equitably settling this competition appears in FIGS. 8 and 9. Each connector has three parts, one part for each code compressor. The parts associated with the same compressor in each connector are linked together in a preference chain so that the higher numbered (as shown) connectors are given preference.

Although the present description involves a single group of senders only, and therefore requires one connector only, other representative connectors are shown in FIG. 9 in order to illustrate the connector preference aspects of the invention.

Returning to the assumed call, in order to minimize the holding time of a code compressor, a connector is activated to select a code compressor at the same time the sender preference circuit is selecting the sender that will be served. Thus, operation of relay 2CST-0 closes a path in the compressor start circuit from negative potential, through resistor 810, operated contacts 2CST-0, normal contacts 17TC, 4TST, 14W, 4TRS, over the connection between points 816 and 818, normal contacts 8CB0, winding of relay 8CS0, conductor 834, normal CS0 contacts of all succeeding connectors, and normal contacts 12CAS-1, 13STB, 13SK, 13TK, 13RR, to ground. This results in the operation of relay 8CS0 which closes a holding path for itself that is independent of the above ground. Note that a pair of normally open contacts in the described series circuit are designated "CST," although they were cited as "operated 2CST-0 contacts." In the circuit, as signified by break-off leads 812 and 814, contacts CST for each of the ten senders served by the first connector are in parallel at this point. Therefore, irrespective of which sender is being served, the corresponding CST contacts will activate the compressor start circuit.

Operation of relay 8CS0 opens chain circuits through the other CS0 relays, causing the release of normally operated check relays 10CAK and 10CSK.

Upon operation of relay 8CS0, closure of the 8CS0 contacts provides an operating path for relay 8CA0 from negative potential, through the windings thereof and operated 8CS0 contacts to ground. The connection of CA0 relays in each succeeding connector to ground, includes normal CS0 contacts of each preceding connector, thus once again preference is achieved.

Operation of relay 8CA0 completes paths from cables 510 and 511 to the first code compressor of the group of three used. This compressor is illustrated in FIGS. 11, 12, and 13. Within the connector itself, energization of relay 8CA0 in combination with the energization of relay 7SA-0 causes the enablement of code compressor check relay 7CCK, and connector busy relay 7CBY; the former

being energized in a circuit comprising negative potential, relay 7CCK, operated contacts 8CA0, and ground; and the latter being energized in a circuit comprising negative potential, relay 7CBY, operated contacts 7CCK and 7SA-0, and ground. Once relay 7CBY operates, it establishes a common connection between itself and relay 7CCK which is effective to insure continuous energization of both relays as long as either 8CA0 or 7SA-0 is operated.

Once relays 7SA-0 and 8CA0 have operated, establishing connection to a compressor, hold relay 13HD is energized therein. The operating path for relay 13HD comprises ground on the winding of relay CL(3812), operated "0" or "1" B register crosspoints, lead 211, diode 229, normal contacts 2CC0, 2CC1, 2CC4, 2CC7 2ASR, 20FR, operated contacts 2CST-0, lead 213, operated contacts 7SA-0, cable 511, lead 213 reappearing in FIG. 13, operated contacts 8CA0, lead 1332, normal contacts 13HD in parallel with current limiting resistor 1335, winding of relay 13HD, diode 1321, lead 832, operated contacts 8CS0 in FIG. 8, normal contacts 8CB0, and lead 821 to the negative potential appearing in the compressor start circuit.

Relay 13HD operates as a "hold" relay to provide an alternate energizing path for the compressor start relays and thereby release the compressor start circuit so that it may prepare for seizure of the other compressors to serve succeeding calls while the first is still being served. Closure of 13HD contacts in FIG. 13 establishes a path from negative potential through resistor 1325 and operated contacts 13HD to lead 832. The negative potential is thus applied through diode 1321, winding of relay 13HD, resistor 1335, operated contacts 13HD, normal contacts 10TRL and 13TIC, and normally operated contacts 13KT1 to ground; and also back over lead 832, operated contacts 8CS0 in FIG. 8, winding of relay 8CS0, and operated contacts 8CS0 to ground. Consequently, both relay 13HD and relay 8CS0 are held up by the negative potential applied to lead 832, and are no longer dependent upon the compressor start circuit.

Operation of relay 13HD in response to selection of a compressor, also causes energization of code compressor busy relay 10CCB0 in a circuit comprising negative potential, the winding thereof, operated contacts 13HD, and ground. In operating, relay 10CCB0 establishes an alternate holding circuit for itself from negative potential, through the winding thereof, lead 830, and operated contacts of the selected CS0 relay to ground. Relay 10CCB0 further furnishes an energizing circuit for the connector busy CB0 relays of its associated compressor, as shown for example in FIG. 8 wherein relay 8CB0 is operated in a circuit including: negative potential, the winding thereof, operated contacts 10CCB0, and ground. Upon operation, relay 8CB0 creates its own holding path comprising negative potential, the winding thereof, diode 838, operated contacts 8CB0, 8CS0, and 2CST-0, and ground. In view of this holding path, connector busy relay 8CB0 will remain operated until both the compressor and the recycle and connector circuits release it, the former via compressor busy relay 10CCB0 and the latter via connector start relay 8CS0 or compressor start relay 2CST-0.

It will be recalled that the first compressor was found idle in the assumed sequence of operations. If this had not been the case, e.g., if another connector had seized the first code compressor, the compressor start circuit would have been connected to the second portion of the connector and consequently bid for association with the second compressor by attempting to operate relay 8CS1. The energization circuit for this second method of compressor seizure is: negative potential, resistor 810, operated contacts 2CST-0, normal contacts 17TC, 4TST, 14W, and 4TRS, terminals 816 and 818, lead 821, operated contacts 8CB0, normal contacts 8CS0, lead 825, normal contacts 8CB1, relay 8CS1, lead 837, normal contacts of the CS1 relays in all succeeding connectors, normal contacts 15CAS-2, STB, SK, TK, RR, and ground. Contacts

8CS0 in the described series circuit prevent a connector from association with two code compressors at once.

Obviously, if circumstances are such that both the first and the second code compressors are busy, the compressor start lead is transferred to the third compressor. Also, the alternate circuit path arrangement is wired to permit continuous search of all compressors until an idle one is found. Thus, if the second and third compressor are busy the first will be selected, even if the wiring between the compressor start circuit and the connector gives preference to the second compressor.

With reference to the holding path for relay 8CB0 to ground through operated contacts 2CST-0, hereinabove described, and the normal contacts of the 8CB- relays connected thereto, it will be noted that any 8CB- relay will be held operated if any other 8CB- relay is normal or if any 8CS- relay is operated. This arrangement is provided to prevent reversion to a more preferred compressor if one should become idle while a less preferred compressor is being seized.

Operation of Code Compressor

Returning to the consideration of the operations of the compressor in response to registration of digits in the sender, it will be understood that cable 510 comprises the leads from the A, B, and C digit registers in the subscriber sender which identify the individual digits. As is well known, and as is described in the aforementioned Carpenter patent, the ten characters possible for each digit are represented by discretely grounding particular ones of four leads for each digit. For convenience, the leads are designated by letter and number; the letter indicating the digit and the number indicating the numerical value of the lead, if grounded. Thus, the character "9" in the A digit register manifests itself by grounding leads A4 and A5. Only the B1 lead is needed from the B register because it is known that the B digit for area codes is either "0" or "1".

As previously mentioned, operation of relay 8CA0 extended the digit register leads to the selected compressor, which in the assumed case is the "first" compressor. Thus, the register leads depicted as going into cable 510 reappear in FIG. 11 wherein they are connected through operated contacts 8CA0 and normal contacts 13RR into the decoder-translator control circuits. It should be remembered, that although the decoder-translator control circuits for each code compressor are shown, the representative register leads from three illustrated senders of one group only are illustrated. It is understood that similar register leads from senders in other groups are similarly connected, as represented by the plurality of leads bracketed "to other connectors."

For description purposes, assume the area code received to be "914." This code manifests itself by grounding register leads A4, A5, B1, and C4. The ground on each of these leads is applied through operated contacts 8CA0, normal contacts 13RR, and windings of relays 11A4A, 11A5A, 11B1A, and 11C4A to negative potential, operating these relays.

Transfer contacts of the decoder-translator control relays provide a grounding path for operation of their associated decoder-translator relays at the upper portion of FIG. 12. Consequently, in response to area code "914" relays 12A4, 12A5, 12B1, and 12C4 operate. Representative transfer contacts of decoder-translator relays 12A1 through 12C5, inclusive, comprise the major portion of FIG. 12. The contacts of each relay are vertically disposed below the winding thereof.

The decoder-translator relays must perform two functions: first, they must decode the area code to determine if it is one of a preselected group, second, if the code is of the preselected group they must translate or compress it into a 2-out-of-5 coded signal discretely representative thereof. Unique interconnections between the contacts

of the decoder-translator relays accomplished the necessary functions.

As illustrated in the present embodiment a decoder-translator is designed to identify and translate ten distinct area codes. Transfer contacts of relays 12A1-12C5 are disposed in ten groups, each group containing a pair of transfer contacts from each relay. Each group is wired to provide a complete path from the upper left lead of the group, e.g. leads 1223 and 1224, to the upper right lead thereof, when a particular area code energizes the decoder-translator relays. Recognizing that in detached contact notation, stationary contacts of a transfer pair appear at the junction between the open and closed contact symbols, and front and back contacts appear at the opposite side of the open and closed symbols respectively, the contacts are connected as follows: the front contacts of relays operated for an assigned code and the back contacts of relays unoperated for that code are connected to the stationary contacts of immediately succeeding relays or in the case of relay 12C5 to an output lead; the remaining back and front contacts are strapped together and connected to the 12A1 stationary contacts in the immediately succeeding group, or in the case of the tenth group, through diode 1226 and winding of relay 12CAS-1 to negative potential. For example, considering the "2" level in FIG. 12, which is wired for area code "914" it will be noted that transfer contacts 12A4, 12A5, 12B1, and 12C4 will be operated. The front contacts of these pairs and back contacts 12A1, 12A2, 12C1, and 12C2 are connected to the stationary contacts of immediately succeeding relays, whereas the back contact of relay 12C5 is connected to lead 1217. Also, the remaining contacts are strapped together and connected via lead 1222 to stationary contacts of relay 12A1 in the "3" level.

With the described wiring arrangement a complete path from the input lead on contacts 12A1 to the output diodes to the right of any group, is possible only when the area code for that group is impressed upon the decoder-translator relays. In all other cases, the circuit path is diverted to the strapped terminals and thence to the succeeding group. In the event the code is not one for which the translator is wired, the circuit path is diverted to the strapped terminals in each group, in chain fashion, and emerges at conductor 1225.

Returning to circuit operation upon connection of the digit register leads to the compressor, energization of relays 12A4, 12A5, 12B1, and 12C4 results in a path from negative potential, through the windings of stabilization relay 13STB and any operated contact of the aforesaid decoder-translator relays, to ground. Relay 13STB has a minimum operate-time that is equal to the difference between the fastest and slowest operate-time of any relay in the 12A1-12C5 group. This insures that all appropriate relays of that group will be operated before the decoding and translating functions are attempted.

Operation of relay 13STB applies ground to the decoder-translator contacts via a path including normal contacts 13SK and 13TK, operated contacts 13HD and 13STB, and normal contacts 13TIC, 10TRL, 12XR, 13XTRL, and 13BL. As previously explained this ground will be extended through closed contacts in the "0," "1," and "2" levels and emerge on lead 1217, thence via diodes 1231 and 1232 to conductors CC2 and CC0, respectively. Conductors CC2 and CC0 become part of cable 1210 and reappear in FIG. 5. The ground thereon is therefore applied through operated contacts 8CS0 and 7SS-0, cable 222, and the windings of compressed code relays 2CC2 and 2CC0 to negative potential.

Relays 2CC2 and 2CC0 operate and provide a locking path for themselves to ground through normal contacts 2ASR and operated contacts 2CST-0 in parallel, conductor 235, and operated off-normal contacts ON1 of the sender. Other compressed code relay contacts, illustrated below each relay of the 2CC0-2CC7 group, are inter-

11

connected to ground lead 219 whenever two relays of the group operate. The contact configuration is arranged to yield a trouble indication if less, or more, than two relays of the 2CC0-2CC7 group operate. Assuming no such trouble, the ground on lead 219 is applied to sender check relay 13SK over a path including: operated 7SA-0 contacts, cable 511, lead 219 reappearing in FIG. 13, operated 8CA0 contacts, normal contacts 12CAS-1, 13XTRL, 12XR, 13BL, operated contacts 13TK1, and diode 1318. Note here, that relay 13TK1 is normally operated in a circuit including negative potential, the windings thereof, and normal contacts 13SK to ground.

Relay 13SK operates and provides a locking path for itself from negative potential, through its windings and operated contacts, lead 1329, and operated 8CA0 contacts to ground.

Reliability Check in Code Compressor

At this point, it will be noted that translation of the area code "914" has been made. However, it is possible that one or more of the decoder-translator relays required for the call failed to operate due to an open register lead. In order to verify the translation, a continuity check of all contacts of the decoder-translator is initiated upon energization of sender check relay 13SK. Operation of relay 13SK releases the ground, appearing at the bottom center of FIG. 12, previously applied via the operated contacts of the decoder-translator to the code compressor relay group, and applies that same ground through operated contacts 13SK, lead 1231, operated contacts 8CA0, lead 214, cable 511, lead 214 as it reappears in FIG. 5, operated contacts 7SA-0, lead 214 to lead 237, and through operated contacts 2CST-0 to lead 238. Leads 237 and 238 are interconnected with the A and B and C digit registers respectively, to transfer the ground thereon to all register leads not originally grounded by the area code registration. In the case being considered these leads are A1, A2, C1, C2, and C5. The new ground condition on the register leads is transferred via cable 212, operated 7SA-0 and 8CA0 contacts, and normal 13RR contacts to relays 11A1A, 11A2A, 11C1A, 11C2A, and 11C5A, causing them to operate. In turn relays 12A1, 12A2, 12C1, 12C2, and 12C5 operate. Now, therefore, all decoder-translator relays should be operated.

Relays 12A1 to 12C5, as well as several others herein disclosed, are of a fast operate multi-contact variety in order to insure the completion of calls within the interdigital time. The high currents which they require preclude operation in multiple under control of a single contact such as the contact of relay 13SK above, as it would be damaged thereby. Relays 11A1A to 11C5A, which are of higher resistance, are therefore employed to repeat the signals from the register leads.

To insure reliable operation several checks are simultaneously made which are designed to prove whether or not all 11A1A-11C5A relays and all 12A1-12C5 relays are operated. Relay 13TK will operate only if all 12A1-12C5 relays are operated, and then over a path including negative potential, its winding and normal contacts, operated contacts 12C5-12A1 in series, operated contacts 13HD, normal contacts 13XTRL and 13BL, operated contacts 13SK, leads 1330 and 1326, and operated 8CA0 contacts to ground. Once operated, relay 13TK locks itself to lead 1326. Because each decoder-translator relay has a pair of contacts in series in the above-described operating circuit, operation of relay 13TK indicates the energization of every decoder-translator relay.

In order to guarantee that a shorted pair of contacts in the aforescribed series chain does not give a false indication, an additional check is provided by relay 13TK1. This relay, under normal conditions, is operated between seizures of the code compressor with which it is associated. It will be noted that relay 13TK1 has a path when

12

relay 13SK is unoperated through the normal contacts thereof, to ground. This path is supplemented prior to energization of relay 13SK by several paths: particularly, one from negative potential, through its windings and operated contacts, over lead 1212, and through normal contacts 11A1A-11C5A in parallel to ground; also, one from negative potential, through its windings and operated contacts, lead 1331, and through normal contacts 12A1-12C5 in parallel to ground. Consequently, only when all decoder-translator control relays, and all decoder-translator relays are operated, will relay 13TK1 be released. Operation of relay 13TK and release of relay 13TK1 remove ground at their contacts from the winding of relay 13HD. This relay, however, remains operated due to ground on lead 213 from the recycle circuit.

Recycling of Subscriber Sender Registers

Operation of relay 13TK and release of relay 13TK1 indicates that the decoder-translator circuit is functioning properly and that the translated code is a valid one. At this time therefore, the compressor circuit may be released. Because a preselected area code ("914") has been detected and compressed, recycle relay 2RCY will be operated to cause recycling of the A, B, and C registers preparatory to receiving the fourth, fifth, and sixth digits of the called destination. Relay 2RCY is energized over a path from lead 219 to FIG. 13, which previously was shown to be grounded by the code compression relays in the recycle circuit of FIG. 2. Continuing the circuit path from conductor 219 as it appears in FIG. 13, it comprises: normal contacts 12CAS-1, 13XTRL, 12XR, 13BL, and 13TK1, operated contacts 13TK, normal contacts 12CAS-1, operated contacts 8CA0, lead 216 in cable 511, operated 7SA-0 contacts in FIG. 5, lead 216 as it appears in FIG. 5, normal contacts 2RCY and 2ASR, the winding of relay 2RCY and negative potential.

In operating, relay 2RCY opens the grounding path for the A(3816) and AA(3815) hold magnets in the subscriber sender thereby causing them to release. This release in turn, causes the release of the B and C hold magnets, as will be understood from a consideration of Patent 2,235,803. In this manner, the recycle of the A, B, and C registers is accomplished. Relay 2RCY also, in an obvious path, provides a ground to operate relay RA2 (3705) in the sender, which initiates reset of the digit directing mechanism so that the succeeding (fourth) digit is directed to the A register rather than to the "thousand" register. Relay 2RCY also further opens the DST (3106) relay ground lead, in order to insure that the marker connector cannot be seized until the recycle process has been completed. To guarantee full release of the A(3816) and AA(3815) hold magnets and the recycling attendant thereupon, relay 2RCY locks to the ground which originally had kept those magnets operated.

Restoration of Code Compressor

Coincidentally with the operation of recycle relay 2RCY, the decoder-translator circuit is restored and prepared for operation in response to succeeding calls. Immediately following operation and release of translation check relays 13TK and 13TK1 respectively, which signals the completion of an accurate translation, register relay 13RR is operated. The energization circuit for relay 13RR comprises: negative potential, winding and normal contacts thereof, operated contacts 13TK, released contacts 13TK1, leads 1330 and 1326, and operated contacts 8CA0 to ground.

As illustrated in FIG. 11, opening of normally closed contacts 13RR disconnects the operating ground supplied to relays 11A1A-11C5A over the register leads A1-C5. Consequently, these relays are released and in turn, release their associated 12A1-12C5 relays. When all relays of the decoder-translator group have released, stabilizing relay 13STB is de-energized by the removal of ground

13

from its operating path. The decoder-translator is thus restored and available for service on subsequent calls.

While relay 2RCY is effecting the subscriber sender operations, the release of the recycle circuit is simultaneously taking place, initiated by release of compressor start relay 2CST-0 in response to the opening of normally closed contacts 2RCY in its energization path, the path parallel to these contacts comprising normal contacts of relays 2CC- having previously been opened. Release of relay 2CST-0 opens the operating path of sender start relay 7SS-0 which in turn opens the operating path of relay 7SA-0. Release of relay 7SA-0 opens one of the operating paths of connector busy relay 7CBY and of code compressor check relay 7CCK.

The same 2RCY contacts which open the energization circuit of relay 2CST-0 in FIG. 2 remove the ground from the energization circuit of hold relay 13HD, causing it to release. Release of relay 13HD, in turn removes the holding potential from lead 832 and therefore causes de-energization of compressor start relay 8CS0.

Release of relay 8CS0 has a multiple effect in that: it effects the opening of the operating path of its associated relay, 8CA0; it re-establishes the ground on lead 835 which allows chain check relay 10CAK to return to an operated state; and it opens the holding path of code compressor busy relay 10CCB0 returning it to an unoperated state. Upon release, relay 10CCB0 opens the grounding path of all connector busy relays (CB0).

Because speed of operation is essential in the instant circuitry, it will be recalled that many operating paths are established from two ends of the connector at once. This technique is also used to accelerate the break-down time of the circuitry after it has performed its function. Release of relay 8CA0 severs connections between the compressor and connector and in so doing further disconnects the operating paths of many relays already de-energized, or in the process of de-energization, because relays 7SS-0 and 7SA-0 are also released. The relays so affected include 7CBY and 7CCK. Release of relay 8CA0 also causes de-energization of sender check relay 13SK, translator check relay 13TK, and register release relay 13RR.

Once relay 13SK is restored, translator check relay 13TK1 reoperates in a circuit comprising negative potential, the winding thereof, normal contacts 13SK, and ground. Chain-check relay 10CSK will also resume its energized state following release of the above-described relays in a circuit comprising negative potential, the winding thereof, lead 833, normal contacts of all CS0 relays, lead 834, normal contacts 12CAS-1, 13STB, 13SK, 13TK, and 13RR, and ground.

Alternation of Code Compressor Start Leads

Throughout the circuit description, it will be observed that many means are provided for alternative paths of access to the three compressors. This, of course, is essential in view of many subscriber senders being serviced. There is extensive use of preference arrangement in order to facilitate the objective of fair allotment of compressor time to each group of senders. Because, by its very nature, a preference arrangement results in increased use of the particular unit preferred, that unit tends to receive extra wear. To obviate the effect of this condition, straps are provided for connecting the compressor start circuits to the connectors, rather than permanent circuit paths. These straps are changed in accordance with any regular schedule in order to insure variations in the particular compressors having initial and secondary preference.

In addition to this manual means of obtaining equalization of code compressor use, the compressor initially preferred in each instance is alternated under the control of the compressor start circuit. Preparation of the compressor start circuit for subsequent calls is initiated under control of traffic control relays 17TC and 17TC1. Operation of relay 13HD closes similar operating paths for

14

both the 17TC and 17TC1 relays. Choosing the path for relay 17TC1 as a matter of convenience, it will be seen to comprise: negative potential, the winding of relay 17TC1, operated contacts 8CA0, lead 1313, operated contacts 13HD and ground. Both relay 17TC and relay 17TC1 lock to ground over paths including operated contacts 17TC and 17TC1, respectively, and any operated 7SA- contacts of the sender groups served by the first connector.

The compressor start circuit in FIG. 8 has two distinct legs, or circuit branches, emanating from a common negative potential. The upper circuit branch contains normally closed 17TC contacts and the lower branch contains normally closed 17TC1 contacts. Thus, the compressor start circuit is opened upon energization of these traffic control relays. While holding the compressor start circuit open, relays 17TC and 17TC1 change the branch of the circuit that will be operative on the succeeding call by activating relay 14W. Obviously, operation of transfer contacts 14W in the compressor start circuit will result on the succeeding call, in the application of negative potential to terminal 817 rather than 816 as was assumed in the instant case.

Upon operating, relay 14W creates a locking path for itself comprising negative potential, the winding thereof, normal contacts 14Z, operated contacts 14W, and ground. Except under certain conditions as explained hereafter, when the compressor has performed its functions and releases the associated connector, relays 17TC and 17TC1 are de-energized due to release of relays 7SA-0 and 8CA0. At that time an operating path is provided for relay 14Z which consists of negative potential, the winding thereof, normal contacts 14Z, operated contacts 14W, normal contacts 17TC, and ground. Once operated, relay 14Z is retained energized over the following circuit: negative potential, the winding thereof, operated contacts 14Z and 14W, and ground. Relay 14W is also kept operated in a circuit including negative potential, the winding thereof, operated contacts 14Z and 14W, normal contacts 17TC, and ground. Thus, while selecting a compressor for a second area code, relay 14W will be operated and therefore the compressor start circuit will initially attempt to establish association with a compressor via terminals 817 and 819, as illustrated.

Following the seizure of a compressor for the second call, relays 17TC and 17TC1 will operate and open the energization circuit of relay 14W. The effect of this, as previously noted, is to change the start path over which the compressor will be selected for the third call. Upon release of the compressor following service of the second call, the de-energization of relays 17TC and 17TC1 opens the operating circuit of relay 14Z.

Upon the request for a compressor, initiated by a third call, the 14W-14Z circuit will have returned to the state initially assumed and the above-described alternating cycle will thereafter continue.

Operation on a Non-Selected Area Call

In the event the area code registered is not one of the preselected group, the decoder-translator circuit will so determine, and cause operation of relay 12CAS-1. In such a case all of the described operations for seizing a compressor will take place upon detection of the "0" or "1" digit in the B digit register of the sender. As previously described, operation of relays 13STB and 13HB establishes a circuit from ground to the decoder-translator contact chains. This circuit includes: normal contacts 13SK and 13TK, operated contacts 13HD and 13STB, and normal contacts 13TIC, 10TRL, 12XR, 13XTRL, and 13BL. Because the area code is not of the pre-selected group, the contact configuration will successively divert the ground condition to succeeding chains until it reaches conductor 1225 and therefore permits energization of call-auxiliary-sender relay 12CAS-1. Relay 12CAS-1 operates and establishes a holding circuit for itself comprising negative potential, the winding and

operated contacts thereof, lead 1213, operated contacts 8CA0, and ground.

It will be recalled that in the case of a preselected area code, the decoder-translator operated appropriate relays in the compressed code group 2CC0-2CC7 and thereby established a ground on lead 219. Since in this case, a non-preselected area code is being handled, relays 2CC0-2CC7 will not be operated, instead, ground will occur on lead 218 due to normal contacts 2CC0, 2CC1, 2CC2, 2CC4, and 2CC7. This ground condition permits energization of sender check relay 13SK via a path comprising: lead 218, cable 511, lead 218 as it reappears in FIG. 13, operated contacts 8CA0 and 12CAS-1, normal contacts 13XTRL, 12XR, 13BL, operated contacts 13TK1, diode 1318, and winding of relay 13SK to negative potential. Relay 13SK operates and locks to a holding path comprising, negative potential, the winding and operated contacts thereof, lead 1329, operated contacts 8CA0, and ground.

Relay 13SK, in operating, establishes ground on lead 1231 as previously described, and simultaneously removes the ground from the decoder-translator contact chain. By grounding lead 1231, the checking process is initiated wherein all previously unused register leads of the sender are grounded and the operation of all relays 11A1A-11C5A and 12A1-12C5 is checked. Assuming proper operation of the decoder-translator, relay 13TK will operate and relay 13TK1 will release, both over paths previously traced.

Once relays 13TK and 13TK1 have operated and released respectively, the ground appearing on lead 218 in FIG. 13 is extended over the following circuit to permit operation of relay 2ASR: operated contacts 8CA0, 12CAS-1, normal contacts 13XTRL, 12XR, 13BL, 13TK1, operated contacts 13TK, 12CAS-1, 8CA0, lead 223, cable 511, lead 223 as it reappears in FIG. 5, operated contacts 7SA-0, diode 233, and winding of relay 2ASR to negative potential. Relay 2ASR operates, and establishes a holding path for itself comprising negative potential, the winding and operated contacts thereof, lead 235, operated off-normal contacts ON1 in the subscriber sender, and ground.

Relay 2ASR also creates an obvious energizing path for relay AS in the subscriber sender, the operation and functions of which are more fully described in aforementioned Patent 2,867,690. Relay AS is used to connect an auxiliary sender to the subscriber sender in order to handle the call with equipment currently in use.

Coincident with the operation of relay 2ASR, register release relay 13RR operates in a circuit comprising, negative potential, winding and normal contacts thereof, operated contacts 13TK, normal contacts 13TK1, leads 1330 and 1326, operated contacts 8CA0, and ground. As previously described, the decoder-translator relays are returned to normal under control of relay 13RR.

After performing its function of calling for an auxiliary sender to service the incoming call, relay 2ASR initiates breakdown of the interconnections between the recycle circuit, connector, and code compressor. By opening the energization paths of relay 2CST-0 in the lower-right corner of FIG. 2, the 2ASR contacts cause relay 2CST-0 to release, and at the same time remove ground from relay 13HD causing it to release. De-energization of the connecting and control relays follows according to the sequence of operation already described, and consequently the code compressor circuit and connector are made available for subsequent use.

It may be noted that in the instant case the regular operation of a subscriber sender equipped with auxiliary sender apparatus was only momentarily interrupted, and that the interruption permitted translation of the area code in order to determine that an auxiliary sender was required.

Protection and Trouble Indication Circuits

The described sequence of operations illustrate the circuit functioning under ideal conditions. Because two hundred subscriber senders are being served by only three code compressors, it is absolutely essential that close supervision be maintained over the circuit to immediately detect failure or malfunctions and provide alternate service or alarms. The present embodiment contains a plurality of timing circuits which allot a predetermined period within which particular operations must be performed. If these operations are not completed within the allotted period, a check is initiated and if possible alternate provision is made for handling the call in progress. The present embodiment also provides continuously active relay check circuits which monitor various subcircuits to detect false grounds or opens which might lead to an improper code translation and compression. Although some checking and precautionary techniques are inherent in the circuits, as designed, e.g., the double contact and lead arrangement in the sender preference circuit of FIG. 7, others will now be described.

Transfer-Start Circuit

To guard against failure due to a false open condition in one of the leads of the compressor start circuit, a transfer-start circuit is provided. After a preselected period of time has elapsed, if a compressor has not been seized by the connector, the compressor start leads are changed and bidding for a compressor by means of an alternate start lead is initiated.

A transfer-start circuit, such as illustrated in FIG. 4, is provided for each connector. The basic components of this circuit are gas tube 416, timing elements 410 and 411, transfer contacts 14IC, and transfer relay 4TRS. During idle periods, normal contacts 14IC shunt capacitor 410 and resistor 412 and consequently the same potential is applied to anode 427, control anode 428, and cathode 429. The timing period begins when transfer contacts 14IC remove the shunt. The values of resistors 411 and 412, and capacitor 410 are chosen to provide an exponential timing wave that yields a potential difference between control anode 428 and cathode 429, that is equal to the ignition potential after a relatively short delay, for example, 80 milliseconds. Thus, tube 416 is ionized 80 milliseconds after timing commences and transfer-start relay 4TRS is energized. In this way, the compressor start leads may be changed, and a bid for association with another compressor initiated, before a fourth digit is dialed into the subscriber sender.

Considering the cycle of operation of the transfer-start circuit, it will be seen that upon operation of relay 14IC, transfer contacts 14IC remove the short across resistor 412 and capacitor 410 and establish a ground on the upper plate of capacitor 410. The ground is applied via relay 4TRS, normal contacts thereof, and operated contacts 14IC. Capacitor 410 charges in a path comprising positive potential, resistors 411 and 412, capacitor 410, operated contacts 14IC, normal contacts 4TRS, relay 4TRS, and ground. Upon lapse of the preselected timing period, control anode 428 reaches ionization potential with respect to cathode 429 and tube 416 fires. It may be noted that resistor 431 is a limiting resistor of large magnitude and that resistor 412 is of small magnitude in relation to either resistor 431 or resistor 411. Consequently, the potential applied to control anode 428 is substantially that appearing on the lower plate of capacitor 410. Ionization of gas tube 416 creates an energization circuit for relay 4TRS comprising: positive potential, gas tube 416, operated contacts 14IC, normal contacts 4TRS, relay 4TRS, and ground. Upon operating, relay 4TRS removes ground from the upper plate of capacitor 410 and provides a holding circuit for itself consisting of negative potential, its lower winding and operated contacts, contacts 4TM1 and 7CCK in parallel, and ground.

17

Operation of relay 4TRS is effective, as illustrated in the compressor start circuit in the upper portion of FIG. 8, to transfer the start voltage to a different lead, and thus to a different compressor start relay. If, as previously assumed, the first attempt to seize a compressor took place over the upper circuit branch, the operation of relay 4TRS results in closing the lower branch and opening the upper one. The start circuit is now: negative potential, resistor 811, operated contacts 2CST-0, normal contacts 17TC1, 4TST, and 14W, operated contacts 4TRS, terminals 817 and 819, lead 825, normal contacts 8CB1, relay 8CS1, lead 837, normal contacts of all succeeding CS1 relays, normal contacts 15CAS-2, STB, SK, TK, RR, and ground. Relay 8CS1 operates, and in accordance with previously described operations, the second compressor will be seized.

In addition to effecting the transfer of the code compressor start leads, relay 4TRS establishes an obvious operating path for transfer-start-auxiliary relay 4TRS1. Upon operating, relay 4TRS1 establishes a locking path for itself via key 415, causes energization of major alarm relay 4MJN in an obvious circuit, and lights indicator lamp 413. Attendants will appraise this situation to determine whether or not additional action need be taken.

It will be recalled that the transfer-start timing operation was initiated by operation of relay 14IC. The operation of this relay is indicative of the coincident occurrence of several conditions, namely: (1) a bid for association with a compressor has been made; (2) no compressor has been seized; (3) an idle compressor is available; (4) a major alarm condition has not occurred. Each of the above factors is assured by inclusion of the following contacts in the series energization circuit for relay 14IC: 4TM, 17TC in parallel with 17TC1, and 10ABA and 14TCA in parallel with 10ABB and 14TCB. The specific circuitry accomplishing the aforementioned results will now be considered.

(1) Time measuring relay 4TM, is an integral part of the connector timing circuit to be described subsequently. At this point it need merely be pointed out that it is energized immediately following the operation of compressor start relay 2CST-0 over a path comprising, negative potential, relay 4TM, normal contacts 4TRS, 4TST, and 7CCK, leads 342 and 240, operated contacts 2CST-0, and ground. Closure of contacts 4TM is indicative of the request of a subscriber sender for a code compressor.

(2) Traffic control relays 17TC and 17TC1 are associated with the first connector (counterparts appearing for each connector) and are energized following the operation of hold relay 13HD over similar paths comprising, negative potential, relay 17TC or 17TC1, operated contacts 8CA0, lead 1314 or 1313, operated contacts 13HD in parallel with contacts 13TK, and ground. Because hold relay 13HD, as previously described, is energized upon seizure of its associated compressor, operation thereof indicates seizure. Since relays 17TC and 17TC1 are controlled by relay 13HD, their operation will occur only if a compressor is seized. Consequently, placement of normally closed contacts 17TC and 17TC1 in the energization circuit of relay 14IC insures operation thereof only if a compressor has not been seized.

(3) All busy relays 10ABA and 10ABB are located at the right center of FIG. 10. Their energization path includes the series connection of normally open contacts associated with each code compressor busy relay 10CCB0, 10CCB1, and 10CCB2. Thus, in order to operate either 10ABA or 10ABB all code compressors must be in use. The normally closed contacts 10ABA and 10ABB connected in parallel in the energization circuit for relay 14IC insure its operation only if an idle code compressor is available. It should be noted that normally open contacts of slow-release relays 14SRA and 14SRB are in the series energization path of relays 10ABA and 10ABB, respectively. As will be shown in the following, relays

18

14SRA and 14SRB are generally operated in the time period between bidding for a code compressor and the establishment of a connection thereto.

(4) Traffic control relays 14TCA and 14TCB are energized in similar paths. Considering relay 14TCA for convenience, it will be seen that its operating circuit comprises negative potential, resistor 1410, normal contacts 14ALA, relay 14TCA, normal contacts 14SRA, operated contacts 4TM, normal contacts 17TC, and ground. Due to the presence of the 4TM contacts, relay 14TCA will only operate between the period of bidding for a code compressor and establishment of a connection thereto. The presence of contacts 14ALA insures operation only if a major alarm has not occurred due to a trouble condition in the corresponding controls.

Upon operation, relay 14TCA establishes an operating path for relay 14SRA and an alternate operating path for itself. The former circuit comprises negative potential, relay 14SRA, a pair of operated contacts 14TCA, operated contacts 4TM, normal contacts 17TC, and ground; and the latter circuit comprises negative potential, resistor 1410, normal contacts 14ALA, relay 14TCA, operated contacts 14TCA, and 4TM, and normal contacts 17TC. Obviously, if relay 14TCA or 14TCB is operated, a corresponding major alarm has not occurred and consequently the normally open contacts thereof in the energization circuit of relay 14IC impose this condition on the operation of relay 14IC. If relays 14TCA and 14TCB are both normal, trouble is indicated in connection with both branches of the compressor start circuit and relay 14IC does not operate, as the transfer-start feature under these conditions would not be effective.

In summation, the transfer-start circuit functions to time the seizure of a code compressor. If seizure does not occur within a preselected interval and an idle compressor is available, the circuit transfers the start leads in order to initiate a bid for a compressor by means of an alternate lead.

Connector Timing Circuit

An alarm circuit is provided in the present embodiment to protect against an unusually long delay between the request for association with a connector and the actual connection, and between the seizure of a compressor and the release thereof following decoding and translation.

A single timing circuit, illustrated in FIG. 4, is used to perform these functions. As seen, the basic elements of the connector timing circuit are: gas tube 417, RC timing components 419, 422 and 423, triggering contacts 4TM1 and 7CCK and request-connector-alarm relay 4RCA.

Initially, gas discharge tube 417 is non-conducting because all elements therein are at essentially the same potential. Upon operation of relay 2CST-0, however, an obvious energization circuit for time-measure relay 4TM is created, causing it to operate and subsequently causing relay 4TM1 to operate. Operation of relay 4TM1 removes the shorting path previously bridging resistor 422 and capacitor 423 and grounds cathode 426 of tube 417, the ground being applied via relay 4RCA, normal contacts 4RCA, operated contacts 4TM1, and normal contacts 7CCK. Under these conditions capacitor 423 begins to charge in a circuit comprising positive potential, resistors 419 and 422, capacitor 423, normal contacts 7CCK, operated contacts 4TM1, normal contacts 4RCA, relay 4RCA, the ground. Resistor 421 is substantially larger than resistor 422 and resistor 419 is larger than either. The charge appearing at the bottom plate of capacitor 423 is applied to control anode 425. The time constant of the RC circuit is selected to cause a potential of ionization magnitude between control anode 425 and cathode 426 within a period of time roughly equivalent to the minimum interdigit time. When tube 417 fires, relay 4RCA is operated in a circuit comprising, ground, its winding and normally closed contacts, operated contacts 4TM1, normal contacts 7CCK, tube 417 and positive potential. Energization of relay 4RCA results in operation of the

major alarm relay 4MJN and ignition of signal lamp 414, both over obvious paths, and also the establishment of a locking path through normally closed key 415. Operation of the major alarm will obviously invite further attention.

Under normal conditions, before the connector timing period has expired, the circuit connections will have advanced to the point that a compressor has been seized and code compressor check relay 7CCK operated. It may be recalled that this occurs immediately following energization of any CA- relay. From the standpoint of the connector timing circuit, operation of relay 7CCK has two results. First, it opens the grounding path that initiated the timing operation and thereby restores the timing circuit to normal. Second, it releases time-measure relay 4TM by severing the ground thereto supplied over lead 342. Release of relay 4TM removes the operating ground of relay 4TM1 and consequently it too is released.

De-energization of relay 4TM1 in conjunction with energization of relay 7CCK is distinctly indicative of seizure of a code compressor. It is important that the time a code compressor is tied up with any one connector is kept to a minimum, therefore, the connector timing circuit is again activated to monitor the duration of seizure. This time, cathode 426 is grounded via a path comprising operated contacts 7CCK, normal contacts 4TM1, normal contacts 4RCA, and relay 4RCA. In the event the code compressor does not complete the functions of decoding and translation before the connector timing circuit times out, the previously mentioned alarm indications will arise. Once again, however, under normal operating conditions the code compressor will have completed its mission and released the connector long before the timing period has expired. This release manifests itself by de-energization of code compressor check relay 7CCK which in turn re-establishes the short across timing capacitor 423 and resistor 422, and removes the ground from cathode 426.

Recapitulating, the function of the connector timing circuit is to yield an alarm if either the connector takes too long to seize a code compressor, or the connector seizes a code compressor and takes too long before releasing it.

Code Compressor Timing and Alarm Circuits

In addition to the timing and alarm circuits associated with each connector, there are similar circuits individual to each compressor. These circuits are designed to give an alarm and also to "freeze" the operation of the compressor in order to permit trouble analysis, whenever a predetermined maximum time elapses without release of the compressor. Typical failures guarded against by the code compressor protection circuitry include: any falsely open path preventing completion of a call; crossed or grounded receiving leads, detected by relay 12XR; blocked recycle control due to false grounding of a recycle circuit control lead, detected by relay 13BL; crossed or grounded trouble release leads detected by relay 13XTRL; and false ground on the CC- leads while the compressor is idle detected directly by the timing circuit. Whenever any of the mentioned difficulties arise, the compressor timing and alarm circuit is maintained in an activated condition and following a predetermined interval trouble analysis means are summoned.

With the basic operation of the illustrated embodiment in mind, the operation of each of the cited detection relays whenever a ground is placed on their operating path is obvious, consequently a detailed description will not be given. It is important to note however that after operating, thereby signalling an abnormal condition, each relay establishes its own holding path whereby either automatic test equipment or an operator may readily determine exactly where the abnormality arose.

The timing function for compressor trouble indications is performed by the circuitry illustrated in the lower half of FIG. 10. This circuit is designed to commence timing

under a plurality of conditions and to summon aid in the event these conditions are not alleviated within a period of time approximately one-third of a minimum interdigit interval. Timing is initiated by energization of time-measure relay 10TM and consequently may be initiated by operation of any one of relays, 13XTRL, 13BL, 12XR, 13SK, 13HD, 13STB, 12CAS-1, 13TK, or 13RR. Note: operation of the first relays of this list is indicative of a trouble condition, whereas operation of the latter relays is indicative of seizure of the compressor by a connector.

Timing may also be started from other sources such as the ground connections through normal contacts 10CAK and 10TMC, 10CSK and 10TMC, and ground connected to lead 1012 by contacts 13TK1 or from the CC- leads. Relay 10TM is operated upon operation of relay 13HD and is released when the timing circuit actuating ground is removed, thereby releasing relay 10TM1 or 10TIS. The function of relay 10TMC is to delay reclosure of certain timing circuit control ground connections to insure full restoration of the timer between compressor seizures.

Assuming normal operations relay 10TM is operated initially over a path comprising negative potential, its own windings, normal contacts 10TM1, 10TIS, operated contacts 13HD, and ground. Upon operation, relay 10TM shunts out the aforementioned 10TM1 contacts and energizes relay 10TM1 in an obvious circuit. Operation of relay 10TM1 energizes relay 10TM2 and starts the timing circuit.

The basic components of the timing circuit are gas discharge tube 1018 and RC timing circuit 1017, 1015, 1013. As in the case of previously discussed timing circuits, the elements of tube 1018 are normally at the same positive potential due to a shorting path across the timing capacitor 1017. This short is removed upon operation of relay 10TM1 at the same time that a ground is established on cathode 1029. The ground is derived via time-alarm relay 10TA, operated contacts 10TM1, and normal contacts 10TIS. Capacitor 1017 therefore charges in a circuit comprising, positive potential, resistor 1013 and 1015, normal contacts 10TIS, operated contacts 10TM1, relay 10TA, and ground. Resistor 1013 is substantially larger than resistor 1015 and consequently the voltage at the control anode 1028 clearly follows the exponential charging curve. When the ionization voltage is reached, tube 1018 fires and an operating path is established for time-alarm relay 10TA, comprising positive potential, tube 1018, normal contacts 10TIS, operated contacts 10TM1, relay 10TA, and ground.

Upon operating, time-alarm relay 10TA closes an operating path for trouble-indication-start relay 10TIS comprising negative potential, the winding thereof, normal contacts 10TIS, operated contacts 10TM1 and 10TA, and ground. The function of relay 10TIS is to give an alarm indication, and summon automatic equipment which may be furnished to investigate trouble conditions. Relay 10TIS locks up to whatever ground connections were originally employed to operate relay 10TM. Energization of relay 10TIS opens the operating paths of both relays 10TM and 10TA, causing them to release, and in turn release relays 10TM1 and 10TM2. Release of relay 10TM1 while relay 10TIS is operated restarts the timer in a circuit which is obvious in light of the previous description.

After a trouble check has been made, trouble-indication-complete relay 13TIC is energized, either manually or automatically, by closing illustrative switch 1336 in the lower right quadrant of FIG. 13. At this point of operation, it is acknowledged that the code compressor circuit is not functioning properly. In order to prevent loss of the call without customer knowledge, overflow request relay 2OFR is energized. The operating circuit for relay 2OFR under these conditions is: negative potential, the winding thereof, diode 231, lead 217, operated contacts 7SA0, cable 511, lead 217 reappearing in FIG. 13, operated con-

tacts 8CA0, operated contacts 13TIC, and ground. Relay 2OFR locks to ground on conductor 235.

Operation of relay 2OFR effects deenergization of compressor start relay 2CST-0 by opening its operating path in the lower right corner of FIG. 2. Restoration of relay 2CST-0 to normal closes the grounding path for marker start relay DST (3106) in the subscriber sender. Relay DST (3106) then operates in an obvious path and as fully described in aforesaid Patent No. 2,235,803 the marker or decoder is connected to establish connections for the call in accordance with the digits stored in the A, B and C register.

As noted in Patent No. 2,235,803, relay SM3 (3702) is operated each time a digit is registered, and released thereafter. Consequently energization of relay 2OFR while relay DST (3106) is operated makes possible a grounding path for overflow relay OF (4206) upon registration of the third digit. The grounding path comprises released contacts SM3, lead 243, diode 232 and operated contacts 2OFR.

Turning again to Patent No. 2,235,803 it will be seen that operation of relay OF (4206) is followed by energization of auxiliary overflow relay OF1 (4203) and trial relay TR1 (3108). Trial relay TR1 (3108) operates and functions to disconnect marker start relay DST (3106) and subsequently energize trial relay TR2 (3109). In operating relay TR2 (3109) reoperates relay DST (3106) and a second marker is connected. This marker examines leads 3134, 3048, and 3133 (so identified in Patent No. 2,235,803) and finds ground on leads 3134 and 3133 due to operation of relays TR2 (3109) and 2OFR. This grounded condition is uniquely identified with request for overflow and the subscriber is therefore apprised, either by an overflow signal or overflow announcement that the call has not gone through.

A more detailed description of the specific relay operations and functions is available in the cited patent.

Recall, that the trouble, in the assumed case, occurred after the code compressor was seized, consequently, relays 2CST-0 and 13HD were operated, along with the other relays controlled thereby. Relay 2OFR removes the operating ground from these relays and the connector and code compressor are restored to normal as described for a regular call. When the sender restores to normal, relay 2OFR releases due to the obvious opening of its locking path.

Trouble Release

If, for some unusual reason, the code compressor fails to release after the establishment of the 2OFR ground, the timing and alarm circuit will again time out. In this case, however, relays 10TM1 and 10TM2 are not operated and the energizing circuit for relay 10TA is therefore: positive potential, tube 1018, operated contacts 10TIS, normal contacts 10TM2 and 10TM1, relay 10TA, and ground. Once operated, relay 10TA provides an operating path for trouble-release relay 10TRL comprising negative potential, the windings thereof, operated contacts 10TIS, normal contacts 10TM1, operated contacts 10TA, and ground. Relay 10TRL has normally closed contacts in all control leads extending between connector and code compressor; upon operation therefore, all control relays are released due to severance of their operating paths. At the same time, ground is applied via contacts 10TRL in the upper right quadrant of FIG. 13 to trouble release lead 1310 which joins cable 1210, passes through operated contacts 8CS0, emerges as lead 523, passes through operated contacts 7SS0, emerges as lead 241, joins cable 222, reappears as lead 241 in FIG. 2, and applies operating ground to trouble release relay 2TRL.

Relay 2TRL operates and attempts to operate relay 2OFR by extending its own operating ground thereto. It also severs the ground for relays 2CST-0 and 13HD insuring release thereof and consequently releasing all of the code compressor connections.

In summation, failure to rapidly perform the decod-

ing and translating functions due to improper operation of the code compressor is rapidly detected and investigated under the supervision of the compressor timing and alarm circuits. If the trouble cannot be eliminated, emergency measures are instituted to release the code compressor and connector and route subsequently received digits to overflow.

Receipt of Fourth Digit Before Completed Code Compression

The occasion may also arise wherein the fourth digit is dialed before the code compressor has finished decoding and translating the first three digits received. If this were to happen unchecked, the fourth digit would be registered in the thousands register and the first three might subsequently be recycled. Provision is made for calling an auxiliary sender whenever dialing continues and the code compressor has not supplied routing information. In the latter event recycle is canceled.

As previously mentioned, relay SM3 (3702) operates each time a digit is registered and releases thereafter. In order to more fully understand operation of the instant circuitry, without undue study of the cited Patent No. 2,235,803, the following sequence of relay operation may be helpful. Upon receipt of a digit to be registered, and before actual registration thereof, relays SM1 (3700), SM2 (3701), and SM3 (3702) operate in that sequence. The interval of time between the operation of relay SM1 (3700) and SM3 (3702) is in the order of 25 milliseconds. Not until relay SM3 (3702) operates, is the digit locked into registration. Following registration the relays are released. Consideration of the contact configuration in Crossbar Subscriber Sender 0 illustrated in FIG. 1, comprising contacts SM1, SM2, and SM3, shows that lead 243 is grounded following receipt of each digit for approximately 25 milliseconds before registration of that digit. In other words, lead 243 is grounded during operating of relays SM1 (3700) and SM2 (3701) while relay SM3 (3702) is still released. The invention utilizes this condition to prevent loss of a call due to receipt of a fourth digit prior to completion of the code compression operations.

A ground on lead 243 prepares an operating path for auxiliary-sender-request relay 2ASR. The operating path is completed only when a code compressor is connected. Consequently, although lead 243 is grounded every time a digit is dialed, it is only when the fourth digit is dialed that relay 2ASR operates. The operating path is: negative potential, relay 2ASR, operated 2CST-0 contacts, lead 246, diode 244, lead 243, normal contacts SM3, operated contacts SM1 and/or SM2, and ground. Thus, if relay 2CST-0 is operated the code compressor has been requested but has not yet supplied the required routing information. In such an instance, as recalled from the previous description, relay 2ASR operates, establishes a locking path for itself, initiates breakdown of the compressor connections, and causes energization of auxiliary sender relay AS. Relay 2ASR also opens the operating path of relay 2RCY to prevent subsequent recycle. Upon release of relay 2CST-0 with relay 2ASR operated, the locking ground path for relays 2CC0-2CC7 is opened. This results in release of these relays if they had been operated due to the call having been partially processed.

Receipt of Special Service Calls

Attention must also be given to the special service call numbers currently in use. These numbers often contain three digits, the second of which may be a "0" or a "1." Calls employing these numbers do not require code compression or auxiliary sender routing. They are allowed to employ the code compression machinery to avoid complexity. Because of this, such calls might be unduly delayed if a code compressor should not be available. To prevent this, a special timing circuit is employed which is effective a predetermined time after request for a code

compressor to operate auxiliary-sender-request relay 2ASR. This timing circuit contains a thermistor adjusted to furnish a closed circuit following said predetermined time interval. The energization circuit for relay 2ASR under such circumstances is, negative potential, the winding thereof, operated contacts 2CST-0, lead 246, resistor 247, and thermistor 245 to ground. Upon establishment of this circuit, relay 2ASR operates and performs the functions hereinbefore described to release the 2CST-0 relay and thereby allow the call to proceed, and to energize relay AS. An auxiliary sender is not actually connected, however, for calls involving only three digits.

It will be appreciated that this timing circuit by effectively shunting the code compressors in the event a special service code is involved, eliminates the need for decoding-relay-configurations directed toward uniquely identifying special service calls as well as preselected area codes.

Abandoned Call

A condition which must be provided for, and one which may result in equipment tie-up if not considered, is the effect of an abandoned call. If a call is abandoned following the registration of an area code the code compressor circuitry will be associated with the subscriber sender registering the code. In order to provide for orderly release in the event of abandonment, a pair of normally open contacts are added to line relay LR (3100). These contacts are used to establish a ground upon lead 236 whenever relay LR (3100) operates. As described in Patent No. 2,235,803 this operation occurs on abandonment of a call. Thus, upon abandonment of a call following registration of an area code, relay LR (3100) operates and provides an energization path for auxiliary-sender-request relay 2ASR comprising: negative potential, relay 2ASR, operated contacts 2CST-0, diode 234, lead 236, operated contacts LR, and ground. As previously described, relay 2ASR initiates breakdown of the code compressor connections and causes energization of auxiliary sender relay AS. The compressor will be released, but since the call has been abandoned the auxiliary sender will not be called. The circuitry will consequently be restored to normal.

Sequential Access of Connectors to Code Compressors

Throughout the circuit description it has been assumed that only one connector at a time was actively seeking engagement with a compressor. It has also been assumed for purposes of brevity that only one sender of a sender group was bidding for access to a connector at any one time. In actual operation the bid intervals may interlap so that several senders of one sender group may simultaneously bid for access to their connector while senders of different groups are seeking access to their individual connectors. In a situation of this nature the characteristics of the control relays in the connectors become important. If any connector's relays are faster than the others all senders associated therewith will be served prior to consideration of the senders associated with other connectors. In order to prevent this the traffic control elements of this circuit are utilized.

Upon operation of a compressor start relay, e.g., 2CST-0, and the consequent operation of relay 4TM as previously described, traffic control relays TCA and TCB associated with a first connector are energized over similar paths. Following the energization path of relay TCA for illustrative purposes, it will be seen to comprise negative potential, resistor 1410, normal contacts 14ALA, relay 14TCA, normal contacts 14SRA, operated contacts 4TM, normal contacts 17TC, and ground. Operation of relay 14TCA establishes a path for its ground to slow release relay 14SRA. Relay 14SRA thereupon operates in a circuit comprising negative potential, the winding thereof, a pair of operated contacts 14TCA, operated contacts 4TM, normal contacts 17TC, and ground. Attention is

directed to break-off leads 1425 and 1426 which are indicative of similar connections to the TM and TC contacts associated with each of the other connectors of the system. It will be understood that relays 14TCB and 14SRB are simultaneously operating in conjunction with the above-described operations.

If it is assumed that another connector was actively seeking engagement with a code compressor at the time the above-described sequence of events took place it will be obvious that relays 14GCA and 14GCB are operated. The operating paths for these relays are from negative potential through the winding thereof, operated relay contacts 14TCA or 14TCB, operated relay contacts —TC or —TC1, to ground, it being understood that break-off leads 1429 and 1430 denote the connection at that point of TC and TC1 relays associated with each connector of the system. The operation of relays 14GCB and 14GCA is effective to lock-on relays 17TC1 and 17TC respectively when they operate as previously described under the control of compressor relay 13HD.

Referring to the compressor start circuit in FIG. 8 it will be appreciated that the effect of locking the traffic control relays is to prevent any further bidding by subscriber senders of the first connector for association therewith. At the same time however in view of the circuit configuration described, it will be apparent that the compressor start circuits of other connectors are not disabled and they may therefore proceed as under normal conditions. In this way each connector is given a single opportunity to service a single subscriber sender of its group, after which all other waiting connectors are given a similar opportunity. In view of this configuration under the worst imaginable conditions the first connector might have to wait while all 19 of its contemporary connectors are permitted to service a single subscriber sender before being able to service its own second subscriber sender. Once such a busy condition has been alleviated relays 14TCA and 14TCB will be deenergized within each connector and consequently group control relays 14GCA and 14GCB will be de-energized. This eliminates the locking up of the traffic control relays and subsequent subscriber senders may be serviced.

Disablement of Sequential Access Means

In the event the selection sequence above described results in tie-up of a connector for an unreasonably long time, alarm relays 14ALA and 14ALB are energized. This causes severance of the traffic control circuitry from the code compressor and connector and creates a first-come, first served arrangement. Simultaneously, an alarm may be activated.

It has been mentioned that the dual circuitry encountered in the traffic control circuit is a result of the compressor start circuit employed. Relays 14ALA and 14ALB are operated in timing circuits of an identical character. The timing circuits may be considered to be individual to a particular branch of the compressor start circuit. For example, the timing circuit for relay 14ALA monitors the operations conducted under initiation of the upper branch of the compressor start circuit.

A complete understanding of the function and effect of the compressor timing circuits may be obtained from a consideration of the one associated with alarm relay 14ALA.

Initially, gas tube 1417 is disabled due to an equal positive potential appearing on all elements thereof. The reason for this state is the short circuit between the junction of resistors 1412 and 1414, and cathode 1433, created by normal contacts 10ABA, 14TCA, 14CWB, and 14CWA. Operation of any of the relays associated with the above series of contacts (without simultaneous occurrence of several other possible conditions) will initiate the timing period.

The pattern of operation of the previously described timing circuits is again followed by the traffic control

timers. Upon removal of the short across capacitor 1416 and resistor 1415, ground is applied to cathode 1433 and capacitor 1416 charges in a circuit comprising: positive potential, resistors 1412 and 1415, normal contacts 14ALA, relay 14ALA, and ground. Resistor 1412 is of substantially greater magnitude than resistor 1415, and the time constant of the charging circuit described is selected to create a voltage difference of ionization magnitude between control anode 1432 and cathode 1433 after elapse of sufficient time to permit the servicing of a call from each of the twenty connectors. Upon time-out, gas tube 1417 is ionized and provides an obvious energization circuit for alarm relay 14ALA. Upon operating, relay 14ALA severs the traffic control circuitry from the connectors by opening the energization circuits of relays 14TCA, 14TCB, 14CWA, and 14CWB.

Considering the plurality of ways in which the timing cycle may be commenced, first notice the function of calls-waiting relays 14CWA and 14CWB. These relays are energized whenever their branch of the compressor start circuit is used to start the connection of a compressor to a connector, no matter which connector is involved. Thus, it would be entirely normal for relays CWA and CWB to be operated simultaneously, although not due to calls being handled on one connector. Operation of these relays will initiate the timing cycle. It will be obvious that if this causes the timing however, operation of traffic control relay 14TCA in combination with all-busy relay 10ABA will reset the timer to zero. This is because there is a justifiable cause for connector tie-up if a compressor bid is made and all compressors are busy.

Timing in the 14ALA relay circuit may also be commenced by operation of traffic control relay 14TCA or all-busy relay 10ABA. In the former case, time-out would indicate an inordinately long waiting period for service, and in the latter case, time-out would indicate an inordinately long tie-up time of all code compressors.

The material hereinbefore discloses an illustrative embodiment of a code compression concept applied to the control of switching equipment used to direct calls of the direct-distance-dialed variety. This invention provides means for special routing of a relatively large number of calls to preselected areas utilizing existing equipment which has insufficient capacity to operate efficiently on such calls. It also provides improvements upon the basic code compressor arrangement whereby rapid dialing or dialing of special codes is effectively handled without loss of the call or undue tie-up of equipment. The invention, however, contemplates employment of these techniques and arrangements in other embodiments without departing from the invention taught herein.

What is claimed is:

1. In a telephone switching system responsive to directory numbers preceded by area codes, register means for storing said directory numbers and said area codes, translating means responsive to said stored codes for creating a plurality of outputs representative of preselected area codes and a further output representative of all other area codes, encoding means connected to said translating means and operative in response to each of said plurality of outputs to produce an electrical condition on a discrete two out of five conductors, said electrical conditioning uniquely identifying each of said plurality of outputs, checking means responsive to said electrical conditioning and operative to produce a first checking means output when said conditioning appears on two conductors and a second checking means output when said conditioning appears on more or less than two conductors, an auxiliary register, means responsive to said further output for connecting said auxiliary register to receive said directory numbers, means operative in response to said first checking means output to reset said register means to receive said directory numbers, and means operative in response to said second checking means output for connecting said auxiliary register to receive said directory numbers.

2. In a telephone switching system responsive to directory numbers preceded by area identification digits, register means for storing said area identification digits, discrimination means operative in response to storage of preselected combinations of area identification digits to produce discrete outputs representative of each of said preselected combinations of area identification digits and operative in response to storage of all other combinations of area identification digits to produce an additional output, recycling means responsive to said discrete outputs to reset said register means for storage of said directory numbers, an auxiliary register, means responsive to said additional output to connect said auxiliary register for storage of said directory numbers, and means operative in response to receipt of said directory numbers prior to production of said discrete outputs to connect said auxiliary register for storage of said directory numbers.

3. In a telephone switching system responsive to sequentially received call destination identifying digits, wherein called areas are designated by a plurality of digits preceding the exchange and line identifying digits, a plurality of groups of subscriber senders, each sender having individual registers for storing each digit as it is received, detecting means in each sender operative to detect the storage area identifying digits therein, a plurality of decoding means for distinguishing preselected area identifying digits and responsive thereto to produce outputs discretely representative thereof, a connector individual to each group of senders, first preference means activated by said detecting means for selectively connecting each subscriber sender storing digits to an associated connector, second preference means activated by said detecting means and operative simultaneously with said first preference means for selectively connecting said associated connector to a decoding means, traffic control means operative upon activation of said second preference means to inhibit subsequent connections involving said connector until all other connectors associated with senders storing digits have established connections with a decoding means, and means responsive to elapse of a predetermined time interval to sever said traffic control means from the switching system.

4. A telephone system wherein call routing is responsive to directory numbers preceded by area identification digits comprising first register means for storing said area identification digits, discriminating means operative in response to the storage of preselected combinations of said area identification digits to produce discrete outputs representative thereof and operative in response to the storage of other combinations of said area identification digits to produce an additional output, recycling means responsive to said discrete outputs to reset said first register means to store subsequently received digits of said directory numbers, second register means for storing digits of said directory numbers, connecting means energizable to connect said second register means to store said digits of said directory numbers, means operative upon storage of each of said area identification digits in said first register means to prepare an energization circuit for said connecting means, and means responsive to the storage of said area identification digits and effective upon receipt of the first digit of a directory number to complete said energization circuit of said connecting means, whereby the digits of said directory number are stored in said second register means.

5. A telephone system wherein call routing is responsive to area code designations comprising a first, a second and a third digit and line address code designations comprising a plurality of digits including a fourth, a fifth and a sixth digit, said digits being sequentially received; comprising a first, a second, and a third register for storing said first, second, and third digits respectively; means responsive to the storage of said first, second, and third digits for producing discrete outputs representative of each combination thereof, recycling means controlled by said

discrete outputs for simultaneously resetting said first, second, and third registers for registration of said fourth, fifth, and sixth digits respectively; additional registers; connecting means energizable to connect said additional registers for registration of said fourth, fifth, and sixth digits; and control means operative in response to the receipt of said fourth digit to energize said connecting means, said control means being effective only prior to operation of said recycling means.

6. A telephone system in accordance with claim 5 further comprising means operative upon the elapse of a predetermined time to energize said connecting means.

7. A telephone system in accordance with claim 6 wherein said area code designations and said line address code designations are received over a communication path; further comprising means operative in response to a

severance of said communication path to energize said connecting means.
